Abstract

We investigate the impact of neutron capture rates near the $A = 130$ peak on the r-process abundance pattern. We show that these capture rates can alter the abundances of individual nuclear species, not only in the region of $A = 130$ peak, but also throughout the abundance pattern. We discuss the nonequilibrium processes that produce these abundance changes and determine which capture rates have the most significant impact.

PACS numbers: 26.30.Hj,26.50.+x

The origin of approximately half of the solar abundances of elements heavier than the Fe group ($Z \gtrsim 26$) is the astrophysical rapid neutron-capture process known as the r-process [1, 2]. While the basic recipe for generating r-process elements is understood, the production of heavy nuclei through repetitions of neutron-capture and β-decay, much remains to be learned about the nuclear physics and the astrophysics of this process.

On the astrophysics side, a number of environments are under consideration as candidate sites. These include core collapse supernova, e.g. [3, 4, 5, 6], neutron star mergers, e.g. [7, 8], black-hole neutron star mergers, e.g. [9], gamma ray bursts, e.g. [10], and shocked surface layers of O-Ne-Mg cores, e.g. [11, 12]. On the nuclear physics side, there is a lack of experimental data for most of the ~ 3000 nuclei that participate in the r-process since the majority of these nuclei are highly unstable. With the development of radioactive beam technology, an increasing number of these nuclei are now accessible to experiment.

It is well known that there are two pieces of nuclear data that are important for the r-process: beta decay rates and nuclear masses, for a review see [13]. The former has the largest leverage on the abundance pattern since the beta decay rates determine the time it takes to progress from the seed nuclei to the large A nuclei. Thus in traditional environments, such as the neutrino driven wind, the beta decay rates can determine whether an $A = 195$ peak is formed or not. The mass model is generally accepted to be important as well, since the equilibrium abundances along isotopic chains are determined by neutron separation energies, which are in turn determined by the nuclear masses. Thus, the mass model has considerable leverage on the shape of the distribution.

In contrast, neutron capture rates have received relatively little attention. One might be tempted to argue that since the actual values of the cross sections only become important during the last stages of the r-process, i.e. during freeze-out, their impact is limited. However, Surman and Engel [14] pointed out that neutron-capture rates in the $A = 195$ region can influence the r-process abundances in this same region at late times. Additionally, a number of groups [15, 16, 17, 18, 19] have examined simultaneous modifications of all neutron capture rates; Rauscher [15] showed that such modifications can alter the time until the onset of freeze-out. Beun et al. [20] noted that a single neutron capture rate, that of ^{130}Sn, can affect changes throughout the r-process abundance pattern. In this paper we present calculations of the influence of neutron capture rates near the $A = 130$ region on the r-process abundance pattern. We find that the effect is non-negligible, affects nuclei across the entire r-process region, and can be comparable to the distribution uncertainties which stem from different nuclear mass models.

Since there is little in the way of measurements for the relevant neutron capture rates, uncertainties are hard to quantify. A comparison of three different sets of theoretically calculated neutron capture rates [20] shows that most rates vary within a factor of 100, although a handful vary up to a factor of 1000 or more.

The bottom panel of Figure 1 shows two different abundance patterns that we obtain by changing the mass model from ETFSI [21] to FRDM [22]. We use capture rates of [23] with the ETFSI masses and of [24] with the FRDM masses; in both cases we use beta decay rates from Möller et al. [25]. We use a parameterized neutrino driven wind as in [20], with a timescale $\tau = 0.1$ s, a constant entropy per baryon of $s/k = 100$, and initial electron fraction of $Y_e = 0.26$. In the top panel of Fig. 1 we show abundance patterns using the same astrophysical conditions, beta decay rates, and the ETFSI mass model, but with the neutron capture rates of a range of nuclei with $128 < A < 138$ changed by a factor of 100. Since abundance plots are usually made on a log scale, differences in nuclear abundances are better seen on a linear plot. In the middle panel we show percent differences for both scenarios. The average change in abundance is 43% for the neutron capture rates and 52% for the mass model, where the latter effect is due primarily to the differing neutron separation energies.

Neutron capture rates cannot influence the abundance distribution throughout most of the r-process when the temperature, T, and neutron number density, n_n, are high enough for (n,γ) $\leftrightharpoons$ (γ,n) equilibrium. This occurs when the neutron capture rate, λ_n, and the photo-dissociation rate, λ_γ, between two adjacent nuclei are balanced and the abundance distribution along an isotopic chain is determined entirely by the Saha equation. The series of most abundant isotopes for each element as determined by the Saha equation is called the equilibrium r-process path. We determine the actual abundances and path using a dynamical nuclear network calculation [14, 20]. In the dynamical calculation, each set of (n,γ) $\leftrightharpoons$ (γ,n) rates falls out of equilibrium at different points in the simulation. A comparison between the equilibrium path and the actual path provides a measure of how strongly equilibrium is maintained throughout, which we quantify as follows. We calculate an abundance averaged neutron separation energy for the system by two different methods: a) taking the abundance weighted average of the separation energy, $S_{n,actual}$, and b) taking the equilibrium abundance weighted average of the separation energy, $S_{n,eq}$. When the neutron capture and photo-dissociation rates are no longer sufficiently rapid to respond to changes in the equilibrium r-process path resulting from changes in the temperature and/or neutron density, equilibrium fails, individual rates become important, and $S_{n,actual}$ departs from $S_{n,eq}$, as shown in the top panel of Fig. 2.

On the left hand side of this panel, the separation energies are rising as the system moves toward stability at late times. However the photo-dissociation rates are not rapid enough to maintain equilibrium so $S_{n,actual}$ cannot keep pace with $S_{n,eq}$. At this point individual photo-dissociation rates can become important. In particular, the photo-dissociation of nuclei that are highly populated can influence the overall neutron number density. As an example, we consider ^{132}Cd in the baseline simulation of Fig. 2. ^{132}Cd is along the equilibrium and actual r-process path while equilibrium obtains; as $S_{n,eq}$ rises as described above, the equilibrium path shifts to ^{130}Cd. However, the photo-dissociation rate of ^{132}Cd is too slow to fully shift the actual path in the baseline simulation. The photo-dissociation rate of a nucleus $(Z, A+1)$ depends on the capture rate of the nucleus (Z, A):

$$\lambda_\gamma \propto T^{3/2} \exp\left(-\frac{S_n}{kT}\right) \langle\sigma v\rangle_{Z,A} \tag{1}$$

where $\langle\sigma v\rangle_{Z,A}$ is the averaged value of the neutron capture cross section, σ, and the relative velocity, v. We therefore perform a simulation where the capture rate of ^{131}Cd is increased by a factor of 10 and compare with the baseline simulation. With the increased rate, at late times ^{132}Cd is able to photo-dissociate to ^{131}Cd, which in turn promptly photo-dissociates to ^{130}Cd, as depicted in the bottom panel of Figure 2. This late-time shift influences the entire abundance distribution as Cadmium is the most abundant element in this simulation—these dissociations therefore emit a significant number of neutrons that are subsequently captured throughout the nuclear network. In the top panel of Figure 3 we show the number of neutrons captured relative to the baseline simulation for both the $A = 130$ peak and the region above the $A = 130$ peak. The solid line curve decreases sharply, showing that less neutrons are captured in the $A = 130$ peak as compared to the baseline simulation, due to the photo-dissociation effect. There is a corresponding increase in the number of neutrons captured elsewhere.

Returning to the top panel of Fig. 2 we see that $S_{n,actual}$ and $S_{n,eq}$ cross at a slightly later time. At this point $\lambda_\beta > \lambda_n, \lambda_\gamma$ so the increase in $S_{n,actual}$ is primarily due to beta decay. Nevertheless, some capture and release of neutrons is still possible, with $\lambda_n > \lambda_\gamma$

due to the falling temperature. Therefore, a few nuclei that are highly abundant can drain significant numbers of the remaining neutrons from the system. For example, at late times, the nucleus ^{131}Sn becomes highly populated in the baseline simulation because it is on the beta decay chain from a waiting point nucleus at late times, as shown in the bottom panel of Figure 2. The neutron capture rate from ^{131}Sn controls the number of neutrons that are captured on the way to ^{132}Sn. The impact of this drain of neutrons is shown in the bottom panel of Figure 3. This figure shows the number of neutrons captured in a simulation where the neutron capture rate of ^{131}Sn is increased by a factor of 100 relative to the baseline simulation. In the $A = 130$ peak more neutrons are captured and so correspondingly less are captured in the region above the $A = 130$ peak, i.e. the rare earth and $A = 195$ regions. This is the same effect as described in [20].

Changing neutron capture rates creates a situation where more or less neutrons are available for capture across the system at different times during the freeze-out process. This causes shifts in the final abundance pattern that depend on the relative strength and timing of the two effects. We have shown two specific examples, but there are a number of rates that can have these same effects. In order to quantify the impact of individual neutron capture rates, we calculate an average fractional change, F, by summing the differences of all mass fractions, X, of all nuclear species

$$F = 100 \sum_{A} |X_{A,baseline} - X_{A}| \tag{2}$$

for simulations in which only one rate is varied.

Using different nuclear data or different astrophysical conditions can cause shifts in the path, i.e. different nuclei are populated during freeze-out from equilibrium. Therefore, different neutron capture rates can become important. We study the results from a number of different simulations in order to determine the range of rates which can play a role. We perform twelve baseline simulations using six different nuclear data sets:

- FRDM masses and rates, and Möller et al. [26] β-decay rates
- FRDM masses and rates, and Möller et al. [25] β-decay rates
- as above but with experimental data [27] included
- ETFSI masses and rates, and Möller et al. [26] β-decay rates

- ETFSI masses and rates, and Möller et al. [25] β-decay rates
- as above but with experimental data [27] included

and two different outflow timescales in the wind model, $\tau = 0.1$ s and $\tau = 0.3$ s. For each of the twelve baseline simulations we perform 250 additional simulations in which the neutron capture rate of each of the 50 nuclei in Figure 4 is varied by a factor of 10, 50, 100, 500, or 1000. The darkest color squares in Figure 4 represent nuclei for which a factor of 10 in the neutron capture cross section yields a change in the overall abundance pattern, F, of 5 to 20% in at least one of the simulations. Nuclei which require a factor of 50 in order to produce at least a 5% change in the abundance pattern have a medium shade. For uncolored nuclei, no simulation produced a 5% change in the abundance pattern. Increasing the rates of more than one nucleus at a time will compound the effect, producing for example, the 43% change seen in Figure 1. Since odd-N nuclei have smaller separation energies and tend to fall out of equilibrium sooner than even-N nuclei, there is a larger sensitivity to odd-N capture rates as shown in Figure 4.

Studies of astrophysical sites and conditions, future observations, and improved nuclear physics input are important for determining the astrophysical site of the r-process. Presently the most lacking piece of input is on the side of astrophysics theory. Nevertheless, it is advantageous to be able to disentangle which effects arise from astrophysical conditions and which arise from nuclear physics considerations. In addition to beta decay rates and nuclear masses, neutron capture rates also play a role in determining final r-process abundance distributions.

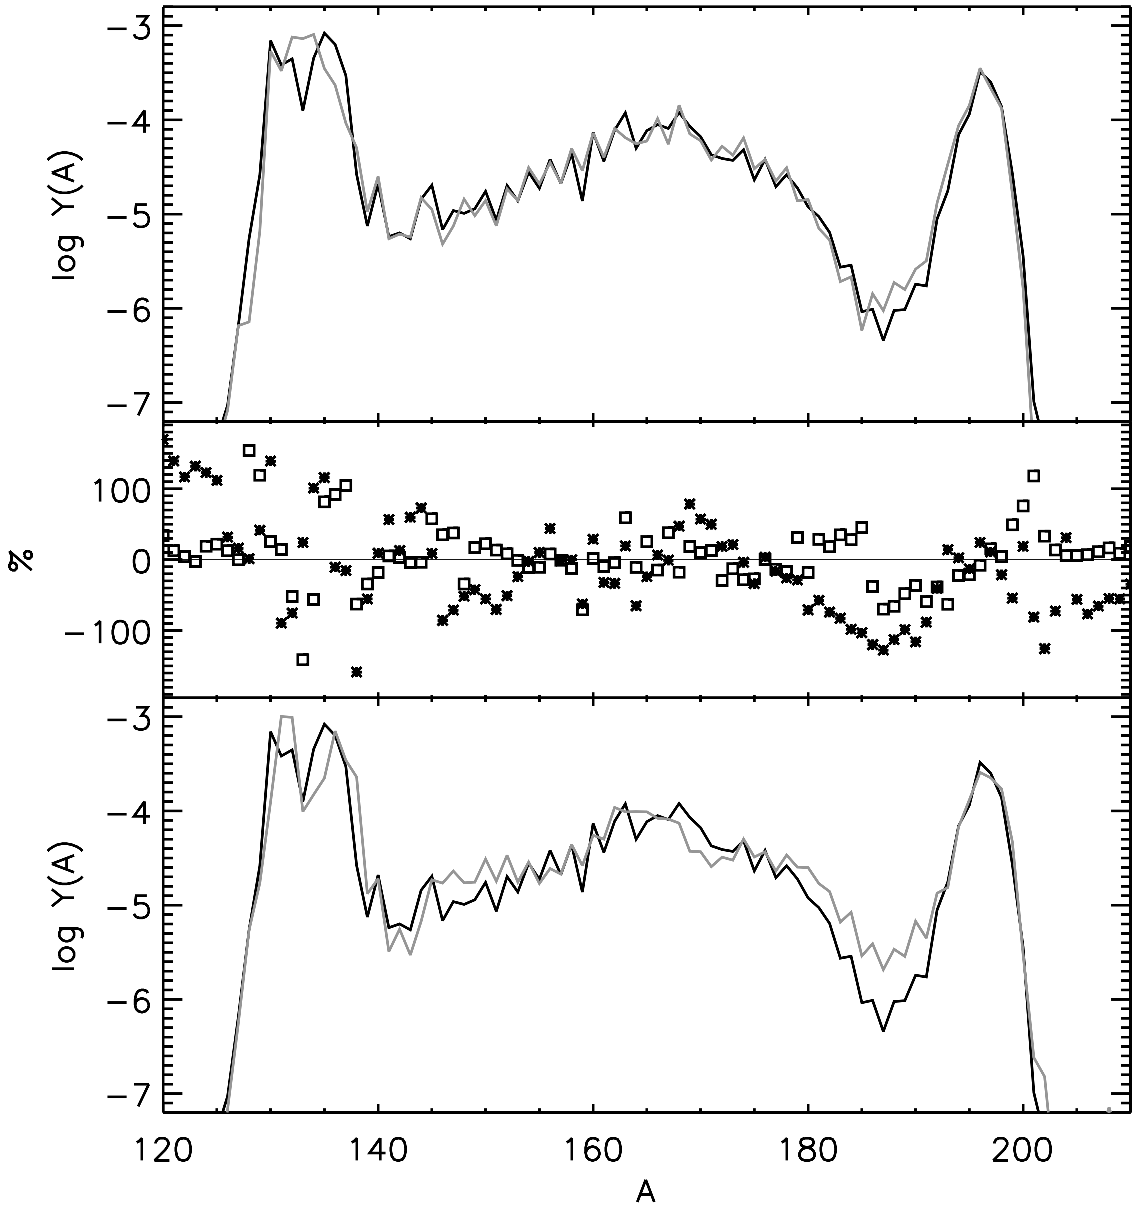

FIG. 1: The bottom panel shows two different abundance patterns that were obtained using the same astrophysical conditions but different mass models. The top panel shows abundance patterns that were obtained using the same mass model, but by increasing fifty neutron capture rates in the $A = 130$ peak region by a factor of 100. The middle panel shows the percent difference in abundance for each point on the curves on the bottom panel (stars) and the top panel (squares).

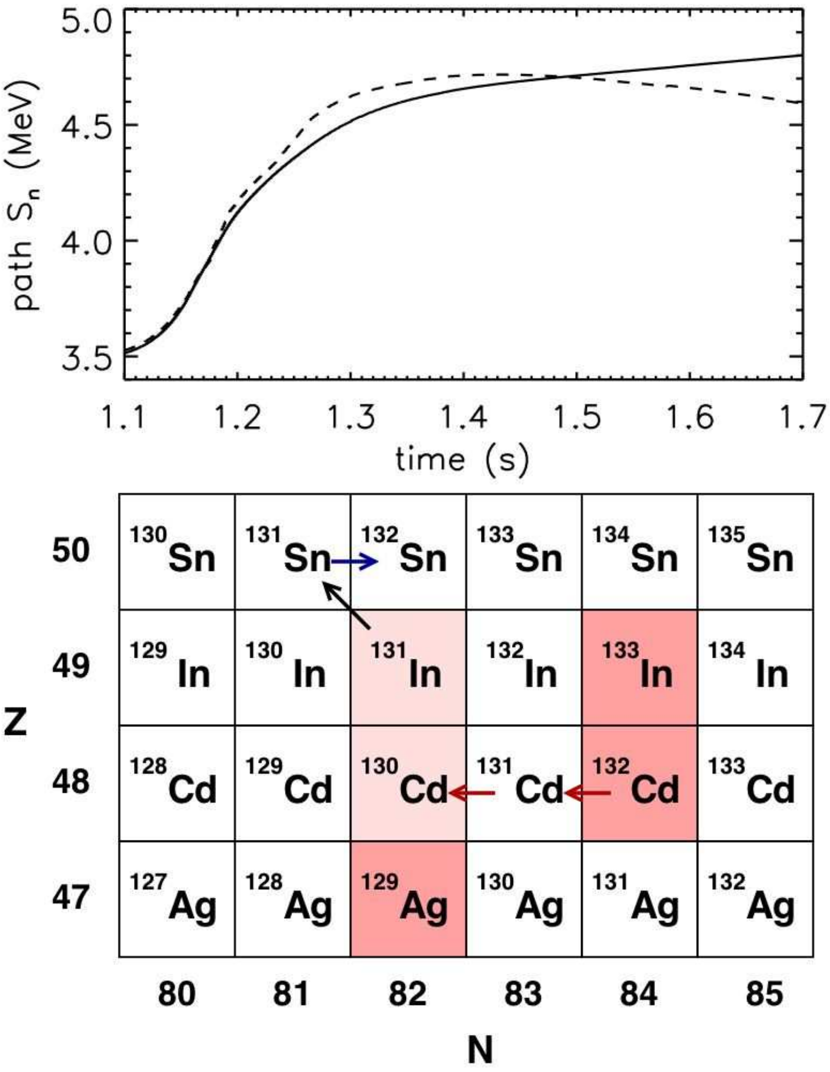

FIG. 2: Top panel: Shows the equilibrium (dashed line) and actual (solid line) separation energies along the r-process path as a function of time for the onset of freezeout in the baseline simulation with FRDM masses and capture rates and conditions $\tau = 0.1$ s, $Y_e = 0.26$, and $s/k = 100$. Bottom panel: Depicts the nuclear flow in the region of ^{131}Sn and in the region of ^{131}Cd for the baseline simulation. Shaded squares show the relevant location of the path: at the beginning of freeze-out from equilbrium ^{129}Ag, ^{132}Cd, and ^{133}In are highly populated and toward the end ^{130}Cd and ^{131}In are highly populated. In color version, red arrows indicate photodissociation, blue arrows indicate neutron capture, and the black arrow shows beta decay.

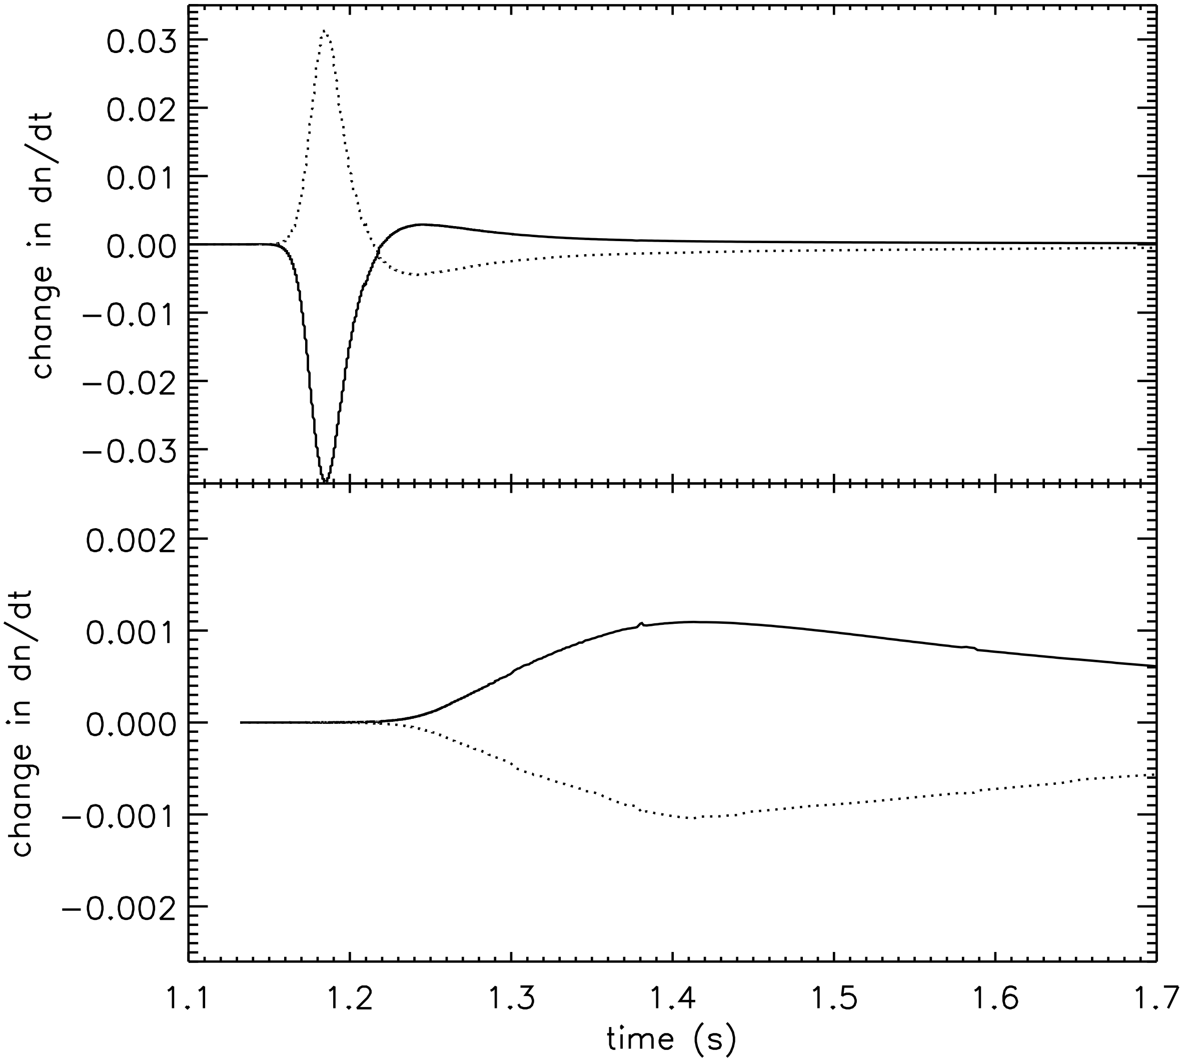

FIG. 3: Top panel: Shows the effect of increasing the rate of ^{131}Cd by a factor of 10 relative to the baseline simulation. The black line shows the rate of neutrons captured in the $A = 130$ region relative to the baseline simulation and the dotted line shows the rate of neutrons captured above the $A = 130$ region. Bottom panel: Shows the effect of increasing the neutron capture rate of ^{131}Sn by a factor of 100 relative to the baseline simulation. More neutrons are captured on ^{131}Sn (and therefore in the $A = 130$ peak - black line), leaving less neutrons to be captured in the region above the $A = 130$ peak (dotted line).
